Abstract

Primary hyperparathyroidism (PHPT) is a disorder of hypercalcemia with inappropriately normal or increased serum parathyroid hormone (PTH) levels resulting from the excessive secretion of PTH from one or more of the parathyroid glands. PHPT is uncommon in infants and children, with an estimated incidence of 2–5 cases per 100,000 population. Patients with PHPT usually present with bone pain, urolithiasis, or nephrolithiasis, and nonspecific symptoms such as fatigue and weakness. Besides, asymptomatic hypercalcemia may also be detected incidentally. Only a few cases of pediatric PHPT have been reported in Korea. We present three patients (a 9-year-old girl, a 14-year-old boy, and a 14-year-old girl) with PHPT who manifested variable clinical features of hypercalcemia. The first and second patients each had a parathyroid adenoma and presented with abdominal pain caused by pancreatitis and a ureter stone, respectively. The third patient had an ectopic mediastinal parathyroid adenoma and presented with gait disturbance and weakness in the lower extremities. All the patients underwent surgical resection of the parathyroid adenoma, and their serum calcium levels were subsequently normalized without medication.

Keywords: Hypercalcemia, Hyperparathyroidism, Parathyroid adenoma
Introduction

Parathyroid hormone (PTH) consists of 84 amino acids that is synthesized and released by the chief cells of the parathyroid glands. It plays an important role in regulating calcium levels and bone homeostasis. PTH secretion is regulated by the concentration of extracellular ionized calcium. In other words, PTH secretion is stimulated by hypocalcemia and suppressed by increased ionized calcium through the interaction with the calcium-sensing receptors. Thus, PTH increases serum calcium level by raising calcium reabsorption in the renal proximal tubules and increasing calcium resorption from bone. PTH stimulates the conversion of 25-hydroxyvitamin D3 [25(OH)D₃] to 1,25-dihydroxyvitamin D3 [1,25(OH)₂D₃] in the kidney, which in turn augments intestinal calcium absorption. In addition, PTH increases urinary phosphate excretion by stimulating fibroblast growth factor 23 release from mature osteoblasts and osteocytes.

Primary hyperparathyroidism (PHPT) is defined as hypercalcemia with inappropriately normal or increased serum PTH levels resulting from the excessive secretion of PTH from the parathyroid glands. An annual incidence of PHPT is estimated to be 3/10,000 in adults between the ages of 50 and 60 years with women being 2 to 3 times more prevalent than men. In contrast, PHPT is relatively uncommon in pediatric ages, with an estimated incidence of 2–5 cases per 100,000 population, regardless of sex. A single benign parathyroid adenoma is the most common cause of PHPT in the general population, including children and adolescents. PHPT is often associated with rare genetic disorders such as multiple endocrine neoplasia 1 and 2A and familial hypocalciuric hypercalcemia.

PHPT may be detected incidentally as asymptomatic hypercalcemia during routine laboratory testing, however, children have a tendency to present with hypercalcemic symptoms, such as bone pain, urolithiasis, nephrolithiasis, or nonspecific symptoms like fatigue and muscle
weakness. Depression, anxiety, and difficulty with memory and concentration are frequently observed in patients with PHPT. Nevertheless, the pathogenesis of these symptoms in hyperparathyroidism remains uncertain.

Measuring serum calcium and PTH levels is helpful to diagnose PHPT. Tests to localize parathyroid adenomas include ultrasonography (US), computed tomography (CT), magnetic resonance imaging, and Tc-99m sestamibi parathyroid scans. Familial hypocalciuric hypercalcemia should be differentiated from parathyroid adenoma because the former generally requires no specific treatment. In patients with PHPT, focused parathyroidectomy to remove parathyroid adenomas is the treatment of choice and is efficient in normalizing serum calcium levels.

Only a few cases of pediatric PHPT have been reported in Korea, and these patients underwent focused parathyroidectomy. We recently encountered three pediatric patients with PHPT caused by single parathyroid adenoma with diverse clinical presentations.

Case report

1. Case 1

A 9-year-old girl presented with recurrent abdominal pain, vomiting, and nausea. She was born at 40 weeks of gestation by normal spontaneous vaginal delivery with birth weight of 2.9 kg. From the age of 7 years, she had suffered from periumbilical pain, generalized weakness, and recurrent vomiting. After the age of 9 years, her symptoms occurred more frequently, and she was referred to our institute. The patient’s height was 129 cm (Korean standard deviation score [SDS] of -0.67), and weight was 22.3 kg (-1.88 SDS). Her vital signs were as follows: blood pressure, 123/74 mmHg; pulse rate, 112 beats/min; respiratory rate, 22 times/min, and electrocardiogram (EKG) result was normal sinus rhythm. Biochemical
findings showed increases in serum calcium level of 14.6 mg/dL (normal range 8.6–10.2 mg/dL) and serum ionized calcium level of 7.2 mg/dL (normal range 3.9–4.5 mg/dL), and decreases in serum phosphorus level of 1.9 mg/dL (normal range 2.5–4.5 mg/dL). Serum intact PTH level was 514 pg/mL (normal range 10–65 pg/mL), the serum 25(OH)D₃ level was 8.9 ng/mL (normal range 30–100 ng/mL), and alkaline phosphatase (ALP) level was 220 IU/L (normal range 81–136 IU/L). A spot urine calcium/creatinine ratio was increased to 2244 mg/g (normal range 16.5–144 mg/g). Her serum amylase and lipase levels were 919 U/L (normal range 30–110 U/L) and 1650 U/L (normal range 13–60 U/L), respectively. Abdomen CT revealed pancreatic swelling and decreased density of pancreatic tail, indicating interstitial edematous pancreatitis (Fig. 1). The serum amylase and lipase levels decreased gradually after intravenous (IV) hydration and fasting for treatment of pancreatitis. However, hypercalcemia was not improved by hydration, furosemide, IV hydrocortisone, or IV pamidronate. On the fifth day of hospitalization, she underwent hemodialysis for two days, which reduced the serum calcium level to 9.6 mg/dL, but this increased again two days later. She had no family history of multiple endocrine neoplasia (MEN). Molecular analysis of the CASR and MEN1 genes did not identify any mutation. A Tc-99m sestamibi parathyroid scan did not identify any parathyroid abnormalities; however, parathyroid US revealed a 1.3 × 0.8 × 2.2 cm-sized, well-defined hypoechoic mass on the posterior of the left thyroid gland in the mid to lower pole, suggesting a parathyroid adenoma (Fig. 2A). She subsequently underwent surgical excision of the parathyroid adenoma. A few hours after surgery, she experienced hypocalcemic tetany with a serum calcium level of 6.7 mg/dL and was treated with oral calcium carbonate (elemental calcium 75 mg/kg/day) and cholecalciferol (1200 IU/day). Following treatment with medication for one month, the serum calcium level has been maintained between 9 and 10 mg/dL without any medication. She showed normal growth rate
of 6.4 cm/year, and reached final adult height of 154 cm (10th–25th percentile; midparental height, 155 cm).

2. Case 2

A 14-year-old girl was brought to medical attention by sudden left flank pain. She was born at term by cesarean section with birth weight of 2.6 kg. The patient’s height and weight were 160 cm (0.14 SDS), and 60 kg (0.96 SDS), respectively. Her vital signs were as follows: blood pressure, 120/75 mmHg; pulse rate, 109 beats/min; respiratory rate, 20 times/min, and EKG result was normal sinus rhythm. The initial serum calcium, phosphorus, and ionized calcium levels were 12.1 mg/dL, 3.4 mg/dL, and 6.38 mg/dL, respectively. The urine calcium/creatinine ratio was 103 mg/g. The serum intact PTH level was elevated to 144 pg/mL, serum 25(OH)D₃ level was 8.2 ng/mL, and ALP level was 405 IU/L. She had no specific family history of MEN. There were no rare sequence variants in the CASR gene. Abdomen–pelvic CT revealed a 6.3 × 5.6 mm-sized stone in the left ureter with obstructive nephropathy. A Tc-99m sestamibi parathyroid scan detected a parathyroid mass at the upper pole on the posterior aspect of the right thyroid lobe. Parathyroid US also revealed a 1.5 × 0.5 × 1.6 cm-sized nodule with increased vascularity in the upper pole on the posterior aspect of the right thyroid gland (Fig. 2B). Extracorporeal shock-wave lithotripsy was performed for the left ureter stone. The patient underwent surgical excision of the parathyroid mass, and the pathological findings demonstrated parathyroid adenoma. Three days after surgery, calcium carbonate (elemental calcium 10 mg/kg/day) and calcitriol (0.75 μg/day) were given for transient hypocalcemia; however, the patient’s serum calcium level returned to normal seven days after surgery, without any medication.
3. Case 3

A 14-year-old boy manifested difficulty walking for two years, which had progressed to weakness in the lower extremities. The patient’s height and weight were 174.4 cm (1.41 SDS) and 59.2 kg (0.27 SDS), respectively. His vital signs were as follows: blood pressure, 110/70 mmHg; pulse rate, 94 beats/min; respiratory rate, 20 times/min, and EKG result was normal sinus rhythm. The initial serum calcium, phosphorus, and ALP levels were 11.2 mg/dL, 3.1 mg/dL, and 1886 IU/L, respectively. The serum intact PTH level was 2984 pg/mL. The serum 25(OH)D3 and 1,25(OH)2D3 levels were 4.6 ng/mL and 69.8 pg/mL (normal range 15–90 pg/mL), respectively. He had no specific family history of MEN. Contrast-enhanced CT to find a mass causing hyperparathyroidism and parathyroid Tc-99m sestamibi positron emission tomography–computed tomography showed a 2.6 × 3.1 cm-sized homogeneously enhancing mass in the anterior mediastinum, abutting the ascending aorta (Figs. 3 and 4). The bone mineral density Z scores of the L-spine and the femur neck were −0.69 (0.661 g/cm²) and −1.94 (0.452 g/cm²), respectively, according to age- and sex-matched Korean references.14

Magnetic resonance imaging of the pelvis to evaluate lower extremity weakness demonstrated a wide sacroiliac joint space and posterior and inferior displacement of the proximal femoral epiphysis with irregular metaphysis and joint erosion, indicating a bilateral slipped capital femoral epiphysis (SCFE). The patient underwent excision of the ectopic parathyroid adenoma, and calcium carbonate (elemental calcium 40 mg/kg/day) and alfacalcidiol (2 μg/day) were given for one month after surgery. However, the intact PTH level was 310 pg/mL with low calcium level (7.7 mg/dL), low 25(OH)D3 level (6.6 ng/mL), and normal ALP level (203 IU/L). Biannual blood tests and parathyroid positron emission tomography–computed tomography were scheduled to monitor the intact PTH and calcium
Discussion

This study described three pediatric patients with PHPT who presented with hypercalcemia. Single parathyroid adenoma was found in two patients, while the other had an ectopic mediastinal parathyroid adenoma, which is rare and found in only 10% of pediatric PHPT cases. Surgical excision of the parathyroid adenoma was performed in all the patients, and their serum calcium levels were subsequently restored to the normal range without medication.

For localization of parathyroid adenomas, non-invasive imaging tools such as US, CT, magnetic resonance imaging, and Tc-99m sestamibi parathyroid scans are generally used. One meta-analysis reported that the sensitivity of high-resolution US was 78% in comparison to 88% in dual-phase Tc-99m sestamibi scintigraphy. However, Tc-99m sestamibi parathyroid imaging has a limitation for detecting small parathyroid adenomas or multiglandular lesions, especially, in case of preoperative normocalcemia. Accordingly, a combination of different imaging modalities is required. Combined US and Tc-99m sestamibi scintigraphy have shown high sensitivity up to 94.5% for preoperative localization of parathyroid adenomas.

PHPT is usually symptomatic in young patients, except for a few young children who are discovered incidentally with asymptomatic hypercalcemia. Nephrolithiasis, nephrocalcinosis, and bone pain are the most common clinical features in pediatric patients with PHPT. Pediatric patients have a tendency to present with hypercalcemic symptoms compared to adults. There is a hypothesis that this may be caused by delay in diagnosis. Unlike most adults who are found to have hyperparathyroidism in routine blood screening, children have little chance of blood screening, so it is possible that the late detection may
affect the deterioration of symptoms.\textsuperscript{21} In addition, the clinical symptoms of children are different from those of adults. For example, bone pain and rickets are common in children and adolescents, while renal stones are generally found in adults.\textsuperscript{24} The prevalence of acute pancreatitis in PHPT is between 1.5\% and 13\%.\textsuperscript{25} The association between PHPT and pancreatitis remain elusive. Notwithstanding, a previous report suggested that the frequency of pancreatitis among patients with PHPT is about 30-fold higher than among the general population.\textsuperscript{26} Symptoms of pancreatitis improve after surgical treatment in most patients with PHPT.\textsuperscript{27} Recently, some experimental evidence suggested that hypercalcemia may cause intrapancreatic trypsin activation and pancreatic damage, which can lead to pancreatitis.\textsuperscript{28}

It has been reported that SCFE is associated with PHPT although the frequency is low. PHPT is an unusual cause of SCFE, with only 11 cases having been reported.\textsuperscript{29} PTH receptors are present in the hypertrophic cartilage zone of the epiphyseal plate. This is the same zone where SCFE occurs. It is possible that the action of PTH on growth plate chondrocytes results in the aberrant cartilage mineralization through its mediators and metalloproteinases, which can extend the duration required for the fusion of epiphyseal plate.\textsuperscript{30} Prolonged elevation of PTH levels result in bone catabolism by elevation of receptor activator of nuclear factor kappa beta (RANKL) and reduction of osteoprotegrin (OPG) levels. Children have higher concentrations of bone biomarkers and faster bone turnover than adults.\textsuperscript{31} These facts can shorten the bone remodeling cycle which protect the integrity of bone from the micro-damages that occur from daily life.\textsuperscript{32}

In conclusion, this study described three pediatric patients with PHPT, which is relatively rare in children and adolescents. Although the clinical features of hypercalcemia are non-specific and diverse, PTHP should be considered in patients with gastrointestinal symptoms, flank
pain, limping, and hip pain. It should be considered that there are various clinical presentations of hypercalcemia in children to prevent complications of hypercalcemia.

**Ethical statement**

This study was approved by the Institutional Review Board at the Asan Medical Center, Seoul, Korea (IRB No. 2019-0880). Informed consent was obtained from all individual participants and participant's parents included in the study.

**Conflicts of interest**

No potential conflict of interest relevant to this article was reported.
